GENERAL INTRODUCTION

This report is a review of drilling carried out on the Mount Nansen Property during the 1971 and 1972 field seasons. Recommendations are made to extend drilling to test a new molybdenite-copper find and three other areas that require further exploration.

Work programs have been carried out on Mount Nansen Mines Ltd. claim block by Area Exploration Company during two summer field seasons. During the 1971 summer months a geologically favourable area for an Arizona porphyry type deposit, was delineated at the northern end of the Property. Geological mapping, geochemical surveys and geophysical surveys were used to locate the anomalous zone. Drilling was undertaken to test parts of the anomaly during the latter months of the 1971 season. A complete summary of this initial work can be found in a report titled, "Mount Nansen Project, Geology, Geochemistry and Drilling 1971 by R. A. Dickinson and P. F. Lewis" and a report by P. E. Walcott, "A Geophysical Report on Ground Magnetic, Electromagnetic and Induced Polarization Surveys." After a review of data, drilling was continued from June to October, 1972.

Diamond drilling was contracted to E. Caron Diamond Drilling Ltd. and percussion drilling (1971) was undertaken by Tonto Drilling Ltd. All core was split and assayed over 10 foot sections for total copper and molybdenum. Generally, every third section was assayed for gold. Bondar-Clegg and Company Ltd., Whitehorse, performed all assaying. The core is stored in the core library of the Department of Indian Affairs and Northern Development, Whitehorse.

GENERAL INTRODUCTION

This report is a review of drilling carried out on the Mount Nansen Property during the 1971 and 1972 field seasons. Recommendations are made to extend drilling to test a new molybdenite-copper find and three other areas that require further exploration.

Work programs have been carried out on Mount Nansen Mines Ltd. claim block by Area Exploration Company during two summer field seasons. During the 1971 summer months a geologically favourable area for an Arizona porphyry type deposit, was delineated at the northern end of the Property. Geological mapping, geochemical surveys and geophysical surveys were used to locate the anomalous zone. Drilling was undertaken to test parts of the anomaly during the latter months of the 1971 season. A complete summary of this initial work can be found in a report titled, "Mount Nansen Project, Geology, Geochemistry and Drilling 1971 by R. A. Dickinson and P. F. Lewis" and a report by P. E. Walcott, "A Geophysical Report on Ground Magnetic, Electromagnetic and Induced Polarization Surveys." After a review of data, drilling was continued from June to October, 1972.

Diamond drilling was contracted to E. Caron Diamond Drilling Ltd. and percussion drilling (1971) was undertaken by Tonto Drilling Ltd. All core was split and assayed over 10 foot sections for total copper and molybdenum. Generally, every third section was assayed for gold. Bondar-Clegg and Company Ltd., Whitehorse, performed all assaying. The core is stored in the core library of the Department of Indian Affairs and Northern Development, Whitehorse.

Appendixed is a review of drilling carried out during the autumn of 1973.

DRILLING, 1971

A total of 2,480 feet of diamond hole and 3,120 feet of percussion hole was drilled on the Property during the 1971 field season. This footage comprises two diamond holes, CD-1 and CD-2, and nine percussion holes, CP-1 to CP-9 inclusive.

CD-1

Started: August 25, 1971

Finished: September 30, 1971

Location: 224N/208W

Dip and Azimuth: 45°, 045°

Elevation: 4,100 feet

Length of Hole: 1,030 feet

Purpose of Hole: To test (a) a general area of silt and soil copper and molybdenum anomalies.

(b) the geological section in toward the silicified dome at 216N/180W.

(c) the extent of quartz-sericite alteration, seen on surface at the confluence of South and East Forks.

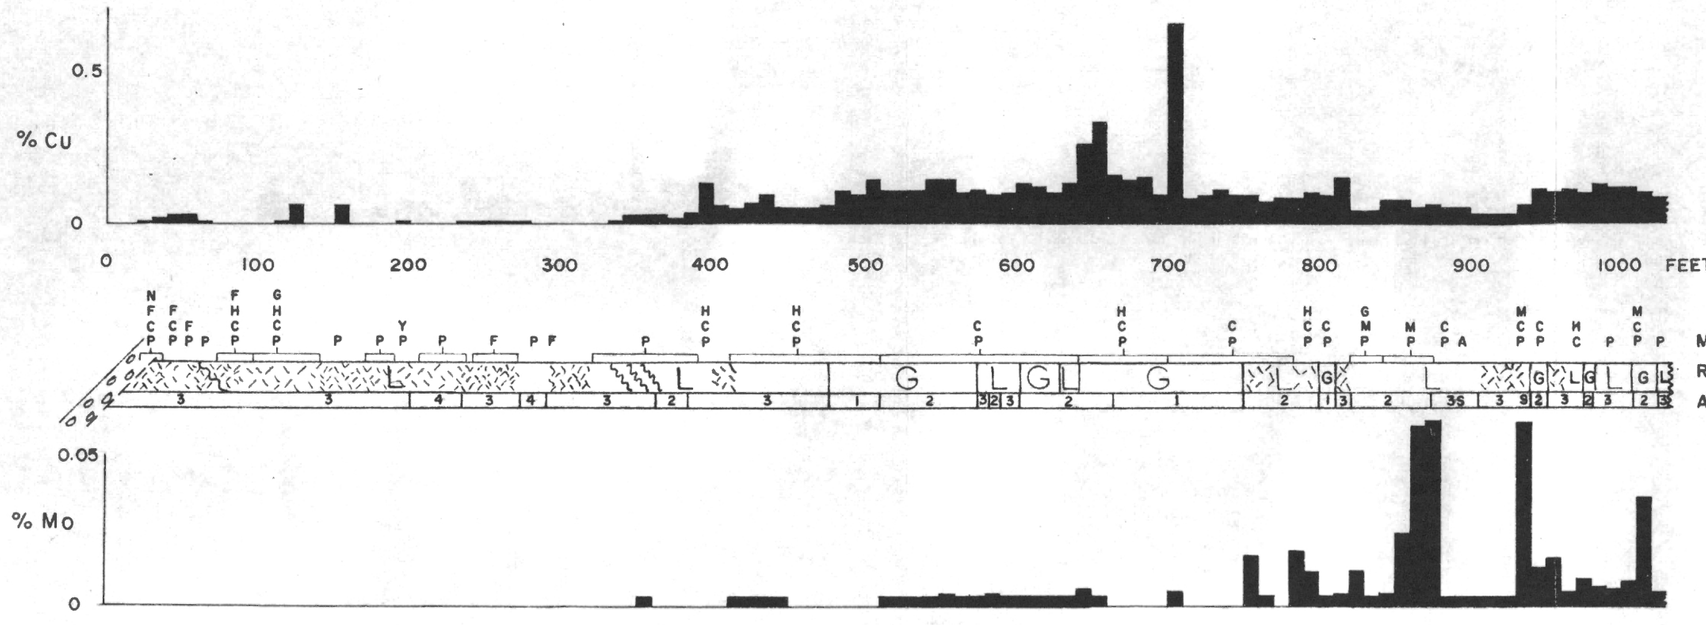

Remarks: The lithology, mineralogy and metal content of the holes is shown on the graphic log overleaf. The following points should be noted:

(1) The presence of breccia as bedrock. This was not noted during surface mapping, thus it may be possible that such unsilicified breccia sub-outcrops over larger areas than thus far suspected.

(2) The presence of fresh granodiorite at depth reaffirming that the extent of the porphyritic rhyodacite intrusion is unknown.

(3) Absence of copper and molybdenum in the top 400 feet of brecciated material and best copper grades in fresh granodiorite.

DIAMOND DRILLING 1971

KEY:

- P - PYRITE
- C - CHALCOPYRITE
- M - MOLYBDENITE
- F - IRON OXIDE
- N - MANGANESE OXIDE
- H - CHALCOCITE
- G - GALENA
- A - ANHYDRITE
- X - MAGNETITE
- Y - CALCITE
- G - GRANODIORITE
- L - QTZ - FELDSPAR PORPHYRY
- BRECCIATION
- FAULT

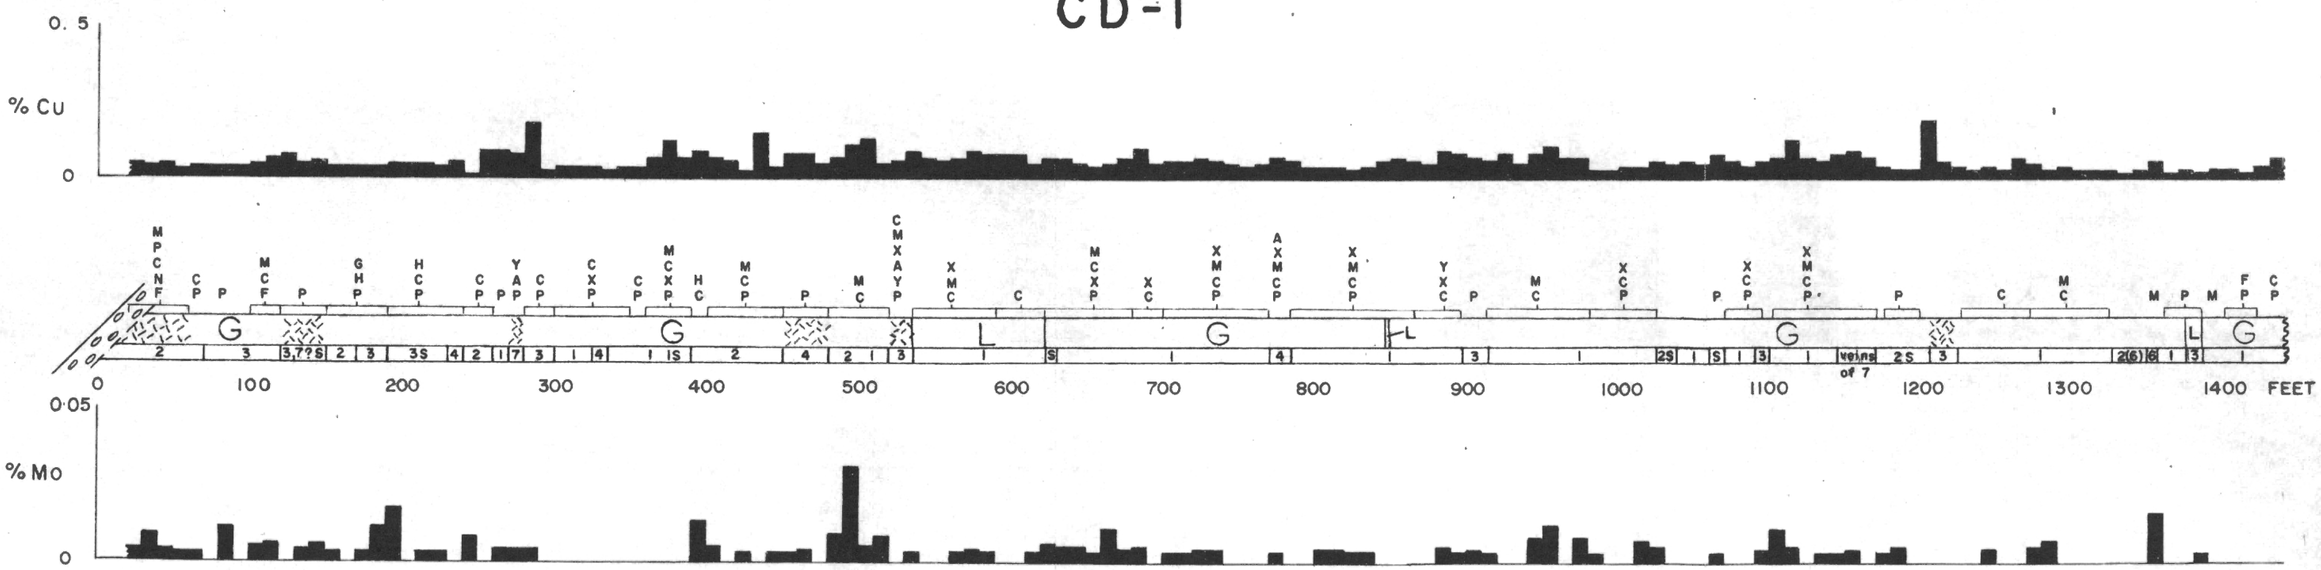

MINERALS NOTED

ROCK FEATURES

ALTERATION FACIES and DIAGNOSTIC MINERALS:

- 1 FRESH
- 2 PROPYLITIC (Chlorite)
- 3 ARGILLIC (Clays)
- 4 ADVANCED ARGILLIC (Clay, Sericite)
- 5 PHYLLIC (Sericite)
- 6 ADVANCED PHYLLIC (Sericite)
- 7 POTASSIC (K-Feldspar)
- S SILICIFIED

CD-1

CD-2

Fig. 1

(4) Antipathetic relationship between copper and molybdenum values, where present, as noted in the soil survey of this area of the Property.

(5) The testing of the section (purpose (b) above) was not achieved due to very difficult drilling and eventual enforced closure of the hole.

(6) No pervasive phyllic alteration was noted.

CD-2

Started: October 1, 1971

Finished: October 7, 1971

Location: 332N/200W

Dip and Azimuth: 45°, 190°

Elevation: 4,200 feet

Length of Hole: 1,450 feet

Purpose of Hole: To test (a) a coincident copper-molybdenum soil anomaly.

(b) a possible westerly extension of a magnetic zone in the granodiorite to the east of the hole.

Remarks: (1) The hole was almost all in granodiorite as expected.

(2) In contrast with CD-1 there is, if anything, a sympathetic relationship between copper, degree of brecciation and molybdenum (note the high coincidence of copper and molybdenum soil anomalies in this area in contrast with CD-1 as well).

CP-1

Started: August 18, 1971

Finished: August 19, 1971

Location: 232N/196W

Fig. 2

Target: Medium copper and molybdenum soil anomalies, the phyllic alteration zone, and an aeromagnetic low.

Remarks: Encouraging grades, especially at around 100 foot depth where some enrichment may have occurred.

CP-2

Started: August 26, 1971

Finished: August 28, 1971

Location: 216N/214W

Depth: 390 feet

Target: Copper anomaly in soils.

Remarks: No encouragement. Again possible enrichment at 100 feet.

CP-3

Started: September 3, 1971

Finished: September 6, 1971

Location: 176N/152W

Depth: 410 feet

Target: Molybdenum anomaly in soils.

Remarks: Low grades, possibly a higher molybdenum to copper ratio than usual.

CP-4

Started: August 20, 1971

Finished: August 21, 1971

Location: 228N/174W

Depth: 270 feet

Target: Copper and lesser molybdenum, anomaly in soils and the margin of a silicified dome.

Remarks: Some encouragement.

CP-5

Started: August 17, 1971

Finished: August 18, 1971

Location: 208N/182W

Depth: 330 feet

Target: Molybdenum anomaly in soils.

Remarks: Higher than usual molybdenum to copper ratio, but grades not encouraging.

CP-6

Started: August 29, 1971

Finished: August 31, 1971

Location: 260N/244W

Depth: 350 feet

Target: Coincident copper and molybdenum anomalies in soils.

Remarks: Grades not encouraging.

CP-7

Started: August 31, 1971

Finished: September 1, 1971

Location: 268N/250W

Depth: 200 feet

Target: Coincident copper and molybdenum anomalies in soils.

Remarks: Some encouragement in copper grades.

CP-8

Started: August 24, 1971

Finished: August 25, 1971

Location: 324N/224W

Depth: 500 feet

Target: Coincident copper and molybdenum anomalies in soils.

Remarks: Grades not encouraging.

CP-9

Started: August 22, 1971

Finished: August 24, 1971

Location: 336N/216W

Depth: 430 feet

Target: Coincident copper and molybdenum anomalies in soils.

Remarks: Grades not encouraging.

General Remarks:

1. Some difficulty was experienced with drilling due to blocky ground and clay-rich horizons.

2. Some enrichment of copper was noted at around 100 feet in some holes.

3. Drilling generally confirms the difference in chemical character of (1) the area of silicified domes, which have non-coincident copper and molybdenum values and (2) the area around the confluence of Nansen Creek or East Fork, which has coincidence of copper and molybdenum.

4. With reference to the I.P. results, analysed after the drilling, Holes CP-3, 4, 8, 9, and CD-2 lie well outside the I.P. halo (see Maps 5 and 6). Holes CP-2, 6 and 7 lie inside the halo and Hole CP-5 lies on its outer edge. Hole CP-1, with encouraging grades, was drilled into the major I.P. anomaly on shallow separations, and Hole CD-1 was drilled into the edge of the halo from the inside and met some encouragement at depth.

DRILLING, 1972

A total of 6,984 feet of diamond hole was drilled on the Mount Nansen Property during the 1972 field season. This footage comprises 12 diamond holes, CD-3 to CD-14. Two 400 foot holes, CD-11 and CD-12, were drilled at the south end of the Property near Pb-Ag-Au vein zones for assessment coverage.

Lithology, mineralogy and metal content of the holes is shown on graphic logs accompanying the following hole descriptions.

CD-3

Started: June 13, 1972

Finished: June 18, 1972

Location: 304+30N/227W

Dip and Azimuth: Vertical

Elevation: 3,775 feet

Length of Hole: 500 feet

Purpose of Hole: To test (a) aeromagnetic low.

(b) a fluvial overburden covered area surrounded by three coincident copper-molybdenum anomalies in soils.

(c) a major intersection of lineaments.

(d) a consistent metal factor anomaly on all four separations.

Remarks: No significant copper or molybdenum assays were returned from CD-3. Traces of supergene chalcocite rimming pyrite were intersected below a 10 foot oxide capping from 94-150 feet. Unlike most other holes, only two consecutive rock types were encountered. Hornblende granodiorite is underlain by rhyodacite porphyry. The extensive length of porphyry core may indicate a porphyry sill contacting with the granodiorite in this area. All other holes except CD-9 intersected narrow quartz-feldspar porphyry dykes cutting batholithic rocks. CD-3 was characterized by erratic changes in intensity of rock alteration, from fresh to strongly argillized. In general the core was mildly-moderately clay altered.

The core was not extensively fractured indicating the postulated structural intersection does not exist.

CD-4

Started: June 18, 1972

Finished: June 22, 1972

Location: 224N/195W

Dip and Azimuth: Vertical

Elevation: 4,100 feet

Length of Hole: 600 feet

Purpose of Hole: To test (a) phyllic alteration zone.

(b) area of encouraging copper molybdenum mineralization as proved by CP-1, 1971.

(c) the major metal factor anomaly on shallow separations.

(d) near major intersection of lineaments.

(e) the edge of major aeromagnetic low.

Remarks: CD-4 intersected significant copper mineralization from 80-220 feet and good molybdenum values from bedrock at 50 feet to the bottom of the hole at 600 feet. Copper assays averaged between 0.2 and 0.3% over the above length and molybdenum averaged 0.0213% over the hole. Supergene chalcocite was concentrated along pyritized shear zones. Sludge samples taken over the supergene zone recorded considerably higher assays than core. Mineralized fractures commonly broke on drilling and mineralization was washed into the sludge. Supergene fluids may have been transported along this fracture system from some distance away.

Quartz diorite, thought to be an early phase of batholithic intrusion,was the predominant rock type intersected. Successive, narrow porphyry dykes cut the quartz diorite over the bottom 300 feet of the hole. These rock types were not intensely altered, in general reaching only an advanced propylitic stage.

CD-5

Started: June 23, 1972

Finished: July 2, 1972

Location: 190N/198W

Dip and Azimuth: Vertical

Elevation: 4,400 feet

Length of Hole: 600 feet

Purpose of Hole: To test (a) inside rim of I.P., metal factor, frequency effect halo.

(b) aeromagnetic low, K_{40} high.

(c) a major lineament.

(d) anomalous copper values in stream silt samples.

Remarks: CD-5, although moderately pyritized did not assay for copper or molybdenum. No chalcocite was logged in this hole but traces of chalcopyrite did occur. Rock types encountered were hornblende granodiorite cut by a series of strongly porphyritic dykes. Large euhedral orthoclase phenocrysts were common. Average intensity of rock alteration was advanced propylitic. Epidote, chlorite and calcite were the main alteration products.

CD-6

Started: July 3, 1972

Finished: July 6, 1972

Location: 199+50N/200W

Dip and Azimuth: Vertical

Elevation: 4,450 feet

Length of Hole: 612 feet

Purpose of Hole: To test (a) silicified and tourmalinized breccia zone.

(b) area within aeromagnetic low and K_{40} high.

(c) area surrounded by streams bearing copper-rich silts and placer gold.

(d) area well inside I.P. metal factor halo (thought to represent pyrite halo).

Remarks: CD-6 intersected a 150 foot oxide capping where jarosite and goethite formed thick coatings on fracture surfaces. Traces of supergene chalcocite were logged although no encouraging copper assays were returned. The 147 foot intersection of tourmalinized and silicified breccia was completely leached and oxidized. Abundant limonite indicates the breccia did carry sulphides. The breccia returned significant gold assays of up to 0.05 oz./ton.

Rock types encountered were tourmaline breccia underlain by granodiorite which was cut by porphyry dykes. Breccia fragments were strongly clay-sericite altered porphyry. The breccia zone appears to dip moderately to the west. Intense clay-sericite alteration, probably in part supergene, appeared in the first 200 feet of the hole. The bottom 400 feet was strongly argillized.

CD-7

Started: July 11, 1972

Finished: July 16, 1972

Location: 204N/195W

Dip and Azimuth: Vertical

Elevation: 4,280 feet

Length of Hole: 500 feet

Purpose of Hole: To test (a) area within aeromagnetic low and K_{40} high.

(b) inside rim of metal factor halo, (thought to represent pyrite halo).

(c) area surrounded by anomalous silts in streams.

Remarks: CD-7 returned low copper assays over its 500 foot length. Supergene chalcocite concentrated along fracture planes from 235-257 feet. Traces of chalcopyrite were logged below the supergene zone. No molybdenite was encountered. Rock type was primarily hornblende granodiorite cut by porphyry dykes. In addition, two black, fine-grained basaltic-looking lamprophyre dykes cut the granodiorite. A mass-spectrograph analysis was run on the lamprophyre rock type and gave the results below:

Aluminum	6.0%	Lead	ND%
Antimony	ND	Magnesium	3.0
Arsenic	ND	Manganese	0.1
Barium	0.1	Molybdenum	ND
Beryllium	ND	Niobium	ND
Bismuth	ND	Nickel	0.01
Boron	Trace	Silicon	Matrix
Cadmium	ND	Silver	Trace
Calcium	3.0	Strontium	0.2
Chromium	0.03	Tantalum	ND
Cobalt	ND	Tin	ND
Copper	0.03	Titanium	0.1
Gallium	0.005	Tungsten	ND
Gold	Trace	Vanadium	0.01
Iron	3.0	Zinc	Trace
Sodium	0.5	Potassium	3.0

Similar lamprophyre dykes were intersected by CD-8 and CD-9. CD-7 averaged a moderately propylitized intensity of rock alteration.

CD-8

Started: July 11, 1972

Finished: July 16, 1972

Location: 180N/190W

Dip and Azimuth: Vertical

Elevation: 4,500 feet

Length of Hole: 850 feet

Purpose of Hole: To test (a) the major metal factor anomaly on deep separations.

(b) the major airborne K_{40} anomaly within the property.

(c) the major aeromagnetic low.

(d) the margin of a silicified porphyry dome.

(e) a topographic high surrounded by drainage giving encouraging silt anomalies in copper and molybdenum.

Remarks: This deep hole met little encouragement and is similar to CD-7 in all respects. CD-8 was moderately to strongly pyritized. Rock type was granodiorite cut by quartz-feldspar porphyry and lamprophyre dykes. Lamprophyre dykes appear to dip steeply. Epidote, chlorite, and carbonates were the main rock alteration products.

CD-9

Started: July 17, 1972

Finished: July 27, 1972

Location: 224N/184W

Dip and Azimuth: Vertical

Elevation: 4,375 feet

Length of Hole: 900 feet

Purpose of Hole: To test (a) large, silicified porphyry dome.

(b) area of strong silicification and clay-sericite rock alteration.

(c) area surrounded by ring of anomalous soils.

(d) for extension of copper-molybdenum mineralization proved by CP-1 and CD-4.

Remarks: CD-9, 1,200 feet northeast of CD-4 and 1,800 feet east of CP-1, returned encouraging copper assays over the section 190'-470' and good molybdenum values from 340'-570'. Supergene chalcocite and locally covellite rimming pyrite were logged below a 275 foot oxide cap to a depth of 585 feet. Brocanthite and malachite were logged in the oxide capping. Similar to CP-1 and possibly CD-4, non-coincident copper and molybdenum assays suggest mineral zoning. Better molybdenum values are commonly found just overlapping or below copper grades. Quartz-feldspar porphyry was intersected over most of the hole, being intruded only by two narrow lamprophyre dykes. The dome structure that CD-9 was drilled into is probably the largest continuous body of quartz-feldspar porphyry on the Property. The porphyry is intensely clay-sericite altered.

CD-10

Started: July 29, 1972

Finished: August 1, 1972

Location: 236N/230W

Dip and Azimuth: Vertical

Elevation: 4,350 feet

Length of Hole: 600 feet

Purpose of Hole: To test (a) a good metal factor anomaly.

(b) a silicified dome.

Remarks: No significant copper or molybdenum assays were returned from CD-10. Supergene chalcocite coating pyrite was logged at 119 feet. Rock types encountered were hornblende granodiorite cut by a series of porphyry apophyses. The core was strongly clay altered. Gypsum (probably supergene) occurred along fractures over the entire hole.

CD-11

Started: August 3, 1972

Finished: August 6, 1972

Location: 7200S/1500W (Mount Nansen Mines Ltd. grid)

Dip and Azimuth: -050°/45°

Elevation: 3,900 feet

Length of Hole: 400 feet

Purpose of Hole: To test (a) geochemical extension of known Mount Nansen Pb-Ag-Au vein zone.

(b) assessment coverage.

and

CD-12

Started: August 7, 1972

Finished: August 9, 1972

Location: 7200S/400W (Mount Nansen Mines Ltd. grid)

Dip and Azimuth: -050°/45°

Elevation: 4,010 feet

Length of Hole: 400 feet

Purpose of Hole: To test (a) geochemical extension of Mount Nansen Pb-Ag-Au vein zone.

(b) assessment coverage.

Remarks: CD-11 and CD-12 were drilled primarily for assessment purposes. The short holes were spotted by B. S. Irmie for Mount Nansen Mines Ltd. on a soil geochemical extension of their Pb-Ag-Au vein zone. The core was left at the camp in the cookhouse for inspection. Yukon Group metamorphics, generally biotite, chlorite schists and feldspathic quartzite were encountered in both holes. Traces of chalcopyrite and malachite were logged.

CD-13

Started: September 22, 1972

Finished: October 6, 1972

Location: 240N/202W

Dip and Azimuth: Vertical

Elevation: 3,950 feet

Length of Hole: 520 feet

Purpose of Hole: To test (a) inside rim of anomalous metal factor halo.

(b) area of coincident copper-molybdenum anomalies in soils.

(c) for extension of mineralized zone proved in CP-1, CD-4 and CD-9.

(d) intersection of major lineaments.

(e) for extension of phyllic alteration zone.

Remarks: CD-13 intersected consistent copper grades of near 0.1% and spotty molybdenum values over its 520 foot length. No supergene mineralization was evident, copper values coming from disseminated chalcopyrite. Molybdenum assays reflect that molybdenite was concentrated locally with quartz stringers. Rock types intersected were quartz diorite cut by narrow porphyry dykes, similar to CD-4 drilled 1,600 feet southeast. The hole was highly broken and altered as it was collared on a major northeasterly-trending fault zone. Some pink orthoclase veinlets characteristic of a potassic alteration facies were cut. Overall the core was strongly clay-sericite altered.

CD-14

Started: October 7, 1972

Finished: October 11, 1972

Location: 288N/220W

Dip and Azimuth: Vertical

Elevation: 3,730 feet

Length of Hole: 502 feet

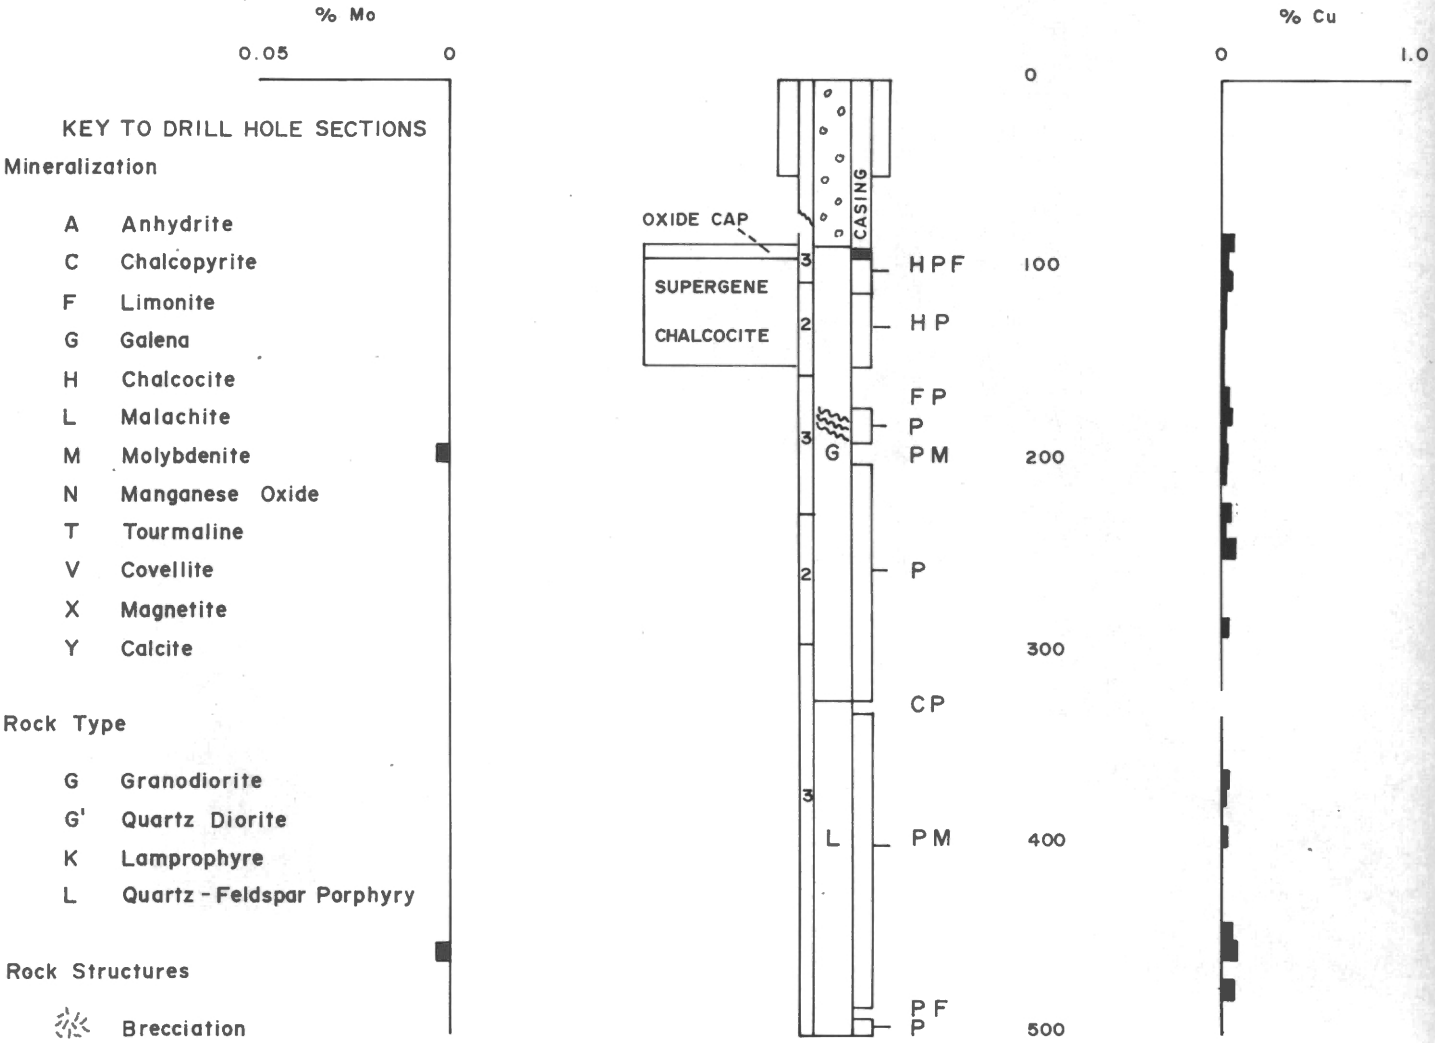

Purpose of Hole: To test (a) inside rim of anomalous I.P. metal factor halo.

(b) area of copper anomaly in soils.

(c) strong intersection of lineaments.

Remarks: No significant copper or molybdenum assays were returned from CD-14. Traces of supergene chalcocite were encountered in the first 26 feet of core. Cobble breccia was intersected over the entire hole. Breccia fragments were subangular, grading from predominantly granodiorite at top to quartz-feldspar porphyry near the bottom. The fragments were welded in a microcrystalline matrix of quartz and minor rock flour. The hole was collared near a structural intersection which suggests the breccia had a cataclastic genesis. The core was strongly silicified and moderately clay altered.

SUMMARY

A total of 9,464 feet of diamond hole and 3,120 feet of percussion hole was drilled during 1971 and 1972 for Area Exploration Company on the Mount Nansen Property. Core recovered by diamond drilling has contributed much to the geological knowledge of the region and in particular of the extensive zone characterized by broad I.P. and geochemical anomalies at the north end of the Property.

Rock types intersected by the 12 diamond holes in this zone are quartz diorite, granodiorite, varying quartz-feldspar porphyries, cobble breccia, and lamprophyre. Fine to medium-grained quartz diorite was intersected by CD-4 and CD-13. Dark, mafic-rich sludge collected from CP-1 suggests this percussion hole also cut quartz diorite. There is no surface evidence for the location of this apparently continuous body in the topographically low brush-covered area of CD-4, 13 and CP-1. The spatial relationship of this rock type to large bodies of granodiorite suggests that the quartz diorite is an early phase of batholithic intrusion.

Coarse-grained granodiorite was the commonest rock type intersected. Hornblende is the dominant mafic mineral, with lesser biotite. The granodiorite is commonly quartz-rich (up to 25%). When intensely altered this rock type appears similar to altered quartz-feldspar porphyry. A distinction can be made by their textural differences. The granodiorite is part of a northwesterly trending batholith (60 miles to the north) radiometrically dated as Cretaceous.

Cutting these batholithic rocks is a swarm of narrow porphyry dykes. It was initially thought that in the anomalous zone the batholithic rock types had been intruded by a few large plugs of porphyry. Every hole except CD-9 intersected a series of porphyry dykes cutting quartz diorite or granodiorite. The porphyry dome into which CD-9 was drilled is probably the largest body of porphyry on the property. The complex dyke swarm appears to trend N30°E with dykes dipping moderately to steeply. N30°E is a dominant lineament direction of the Dawson Range and Property. The prominent linear series of porphyry domes located at the central north end of the Property trends N30°E. Although the dykes appear to be of the same acidic composition, their textures vary considerably. Some are quartz porphyries, others feldspar porphyries with one or two types of feldspar phenocrysts and still others are non-porphyritic, aplitic textured dykes. The most common dyke rock type however is quartz-feldspar porphyry. This rock type is characterized by resorbed quartz eyes and subhedral feldspar phenocrysts set in a grey, siliceous microcrystalline matrix. Mineralization is associated with the porphyry dykes.

Three holes intersected brecciated sections. CD-1 and CD-14 cut strongly silicified breccia while CD-6 intersected tourmalinized and silicified porphyry breccia. The cobble size fragments of CD-14 were mixed granodiorite

and porphyry while the pebble-cobble size fragments of CD-1 and 6 were porphyry. All the breccias had subangular fragments and were near postulated structural intersections suggesting a cataclastic genesis aided by explosive, streaming volatiles. The tourmaline breccia zone at 200N, 200W, on which CD-6 was collared appears to dip moderately to the west.

CD-7, 8 and 9 intersected lamprophyre dykes. The dykes intrude both granodiorite and porphyry rock types. The lamprophyre rock type is commonly black, fine grained and basaltic looking. Like many lamprophyres it is a basic strontium and barium-rich rock. A lamprophyre-granodiorite contact dipped nearly parallel with CD-8 suggesting a near vertical dip for the lamprophyre dykes.

Rock alteration types and intensities are similar to many porphyry copper camps. On a broad scale rock alteration products are probably zoned but each diamond hole was characterized by local erratic changes in alteration intensity. Fracture zones appear to be the primary control of rock alteration both locally and zonally. CD-2, 4, 5, 7 and 8 averaged an advanced propylitic stage of rock alteration. Epidote, chlorite and calcite were the main alteration products. Rock intersected by CD-1, 3, 10, 13 and 14 averaged an argillic stage of alteration. Kaolin and possibly montmorillonite were the main products of rock alteration. CD-6 and 9, cut rock intensely altered to a phyllic stage. Core areas of a broad alteration mineral zoning pattern appear to be the silicified topographic domes located at the north end of the Property.

Rock alteration was more intense near surface than at depth in every diamond hole. Clay minerals especially were common, indicating supergene processes have increased the grade of rock alteration near surface and possibly erased any primary zoning pattern. Gypsum logged in CD-10 along fracture planes probably has a supergene genesis.

Mineralization at the north central end of the Mount Nansen Property is much like that of many porphyry copper deposits of southwest U.S.A. Supergene chalcocite was logged in CD-1, 3, 4, 6, 7, 9, 10, 13 and 14 below a variable thickness of oxide capping. Primary chalcopyrite and molybdenite was commonly logged below the supergene zone. Copper and molybdenum mineralization occurs in all rock types described earlier except the lamprophyres.

The thickest oxide caps were intersected by CD-6 and CD-9. Jarosite and goethite were prominent, often forming thick coatings along fracture planes. Traces of malachite and possibly brocanthite were also found in the cap.

CD-4 and CD-9 intersected significant amounts of supergene copper and returned the best assays of the program. In the supergene zone, chalcocite

and covellite form skins on pyrite. Strongly pyritized sections within the supergene zone return the best assays. The supergene blanket undulates, possibly due to permeable fracture zones controlling supergene fluids. In general the "blanket" begins at an altitude of 4,150 feet A.S.L. and although of variable thickness has been logged down to 3,625 feet A.S.L. Copper grades have at least doubled by supergene enrichment.

Significant molybdenite was intersected by CP-1, CD-4, CD-9 and CD-13. Better molybdenum grades commonly occur at the base of supergene copper zones. The molybdenite often accompanies hairline quartz fracture fillings.

Gold values are associated with the quartz fillings. CD-6 assayed gold values of up to 0.05 oz./ton over a 147 foot intersection of tourmalinized and silicified breccia.

Minor galena and sphalerite veinlets were intersected by CD-1, CD-2 and CD-13.

Soil geochemical results have been the most successful indicators of copper-molybdenum concentrations on the Mount Nansen Property. The large silicified porphyry dome centred at 216N, 176W is surrounded by copper and molybdenum anomalies in soils. Percussion holes CP-1, 4 and 5 and diamond holes CD-4, 9 and 13 have been drilled on the western half of this dome and have all yielded encouraging copper and molybdenum grades.

Induced polarization metal factor and frequency effect anomalies thought to represent an offset pyrite halo have not been effective in delineating copper-molybdenum concentrations. All diamond holes intersected moderately pyritized rock. Core from CD-8, drilled into the strongest metal factor anomaly on deep separations, appeared slightly more pyritized than other holes. Mineralization cut by CD-4 is likely represented by the anomalous metal factor results on shallow separations. However CD-9,which was drilled 1,200 feet northeast of CD-4,intersected similar mineralization which was not outlined by I.P. results. Perhaps poor contacts over silicified portions of the property minimize the use of I.P. results as a guide. The mineralized zone intersected by CP-1, CD-4 and CD-9 appears continuous, contrary to I.P. results.

Finally, several logistical problems are involved when drilling in the Mount Nansen area. Comments are listed below to aid future drilling programs.

(1) Drilling should be limited to the period early June - mid-September when water is readily available.

(2) Vertical holes are drilled much quicker and cheaper than angle holes due to blocky, altered ground.

(3) Casing holes to several hundred feet and drilling with mud is common due to blocky, altered ground.

(4) Waterlines are commonly lengthy due to the fact mineralization is associated with topographic domes some distance away from freely-flowing, low-lying creeks.

(5) Cats heavier than a D-6 are useless. A D-6 with winch is ideal.

RECOMMENDATIONS

Several anomalous zones, favourable for porphyry copper type mineralization remain untested or require further testing by diamond drilling on the Mount Nansen Property. They are:

(1) The eastern half of the large porphyry dome centred at 216N, 176W including its eastern flank.

(2) The broad copper-molybdenum geochemical anomaly located at the northwestern corner of the property and in part lying on ground optioned from Mr. Toni Wheeler.

(3) The new Rusk Creek molybdenum-copper zone.

(4) The borders of a small porphyry dome centred at 196N, 160W.

Suggested locations for drill holes to test these areas are listed below in order of preference.

(1) 216N, 174W (vertical, footage - ≈1,000 feet)

The eastern edge of the largest, silicified and clay-sericite altered porphyry dome.

This hole will test:

(a) Probable continuation and thickening of supergene copper zone (see schematic X-section), proved in CP-1, CD-4, CD-9.

(b) Strong clay, sericite, silica alteration.

(c) Uphill edge of coincident Cu, Mo geochemical anomaly.

This will have to be a deep hole to penetrate the oxide capping. CD-9, a 900 foot hole, is at an altitude 225 feet below this proposed hole. Supergene chalcocite was logged in CD-9 to a depth of 600 feet.

(2) 344N, 216W (vertical, footage - 500-600 feet)

Eastern slope of Caribou Mountain.

This hole will test:

(a) Uphill end of a strong Cu, Mo, Pb geochemical anomaly.

It should be noted that one long angle hole located at 342N, 230W with an azimuth of 0^{o} may be a viable alternative to several vertical holes. CD-2 drilled in this area intersected competent rock and little trouble was experienced. The angle hole would cut across the geochemical anomaly uphill and opposite to CD-2.

(3) 260N, 342W (azimuth 260^{o}, dip 50^{o}, footage - 1,000 feet)

Located on the new Rusk Creek grid (see Rusk Creek Report).

This hole will test:

(a) The geologic section through a pile of biotite-quartz altered dacitic volcanics, probably contacting with a hypabyssal porphyry sill.

(b) Coincident Cu-Mo geochemical anomaly rimmed by high Pb-Zn-Ag values.

No problem with an angle hole should be encountered in this region. The rock appears competent, alteration consisting of quartz-biotite. Little to no supergene enrichment can be expected. Grades may increase towards the contact with the underlying intrusive.

(4) 194N, 162W (vertical, footage - 500-600 feet)

A small silicified dome north of Eva Creek.

This hole will test:

(a) A silicified, clay-sericite altered porphyry dome.

(b) An area surrounded by anomalous soil geochemistry.

(c) An area ringed by anomalous I.P. results.

The geology of this area is similar to that near CD-9 but on a smaller scale. Air photos show the area to be well fractured.

Respectfully submitted,

Robert A. Dickinson

Appendix (v)

DRILLING, 1973

A total of 1,896 feet of diamond hole was drilled on the Mount Nansen property during the autumn of 1973. This footage comprises 3 holes, CD-15 to 17. Lithology, mineralogy and metal content of the holes are shown on the graphic logs accompanying the hole descriptions given below.

The 1973 drilling program was designed to test areas of relatively low soil geochemical response that were ringed by higher responses strongly anomalous in copper and molybdenum. Previous drilling had shown that these strongly anomalous zones did not overly the best mineralization, whereas comparision with certain other porphyry environments, e.g., Tyrone, New Mexico, supported the concept that the best values might underly such areas of low response. This concept was supported by the results of hole CD-9.

Three such geochemical rings exist on the Mount Nansen property, coincident with the areas of strongest overall geochemical response. These are:-

1) the area at the headwaters of the South and East Forks of Nansen Creek, where previous drilling (CP-1 and 4, CD-4 and 9) has yielded encouraging results.

2) the Rusk Creek area, not previously drilled, which was the subject of reconnaissance surveys in 1971 and detailed geochemical survey in 1972. This area shows the effect of porphyry-type mineralization in andesitic volcanic host rocks rather than in granitic intrusive as elsewhere on the property.

3) the area north of the confluence of Summit and Nansen Creeks on the south slope of Caribou Mountain. Previous drilling of spot highs in the ring of anomalous copper and molybdenum values has not indicated ore-grade mineralization.

The rings in these 3 areas were tested by holes CD-15, CD-16 and CD-17 respectively, as described below.

CD-15

Started: September 16, 1973

Finished: September 20, 1973

Location: 206N/165W

Dip and Azimuth: Vertical

Elevation: 4,360 feet

Length of Hole: 693 feet

Purpose of Hole: To test (a) good molybdenite mineralization exposed in a trench

(b) the inside edge of a ring of copper and molybdenum soil anomalies

Remarks: CD-15 intersected minor but consistent copper values (approx. 0.1%) over the first 500 feet, and minor molybdenum values (0.025%) in the following intersections of altered granitic intrusive: 50-200 feet, 470-530 feet and 590-690 feet. Notably different mineral parageneses were apparent - copper occurring generally as chalcopyrite coating late fracture surfaces and as a trace dissemination, whereas molybdenite is associated with silica flooding and veining after argillic alteration of the host rocks. Two phases of silicification, one pre and one post-porphyry intrusion, may account for the lack of molybdenum in the porphyry.

CD-16

Started: September 23, 1973

Finished: September 28, 1973

Location: 266N/344W

Dip and Azimuth: -60°, 290°

Elevation: 4,400 feet

Length of Hole: 600 feet

Purpose of Hole: To test (a) the centre of an area of lower copper and molybdenum soil values ringed by higher values,

(b) the general geological environment of the untested Rusk Creek area,

(c) the centre of a crude, concentricly zoned, silt survey anomaly pattern, with copper-molybdenum in the centre grading outward to lead, zinc and silver.

Remarks:- CD-16 was very weakly mineralized throughout,

with trace copper, molybdenum, zinc and lead occurring in late pyritic veinlets. The whole intersection was of highly altered feldspar porphyry, probably originally andesitic dykes and flows of the Jurassic Mount Nansen Group, as opposed to the granitic plutons and porphyries to the east. Common alteration assemblages were silica-biotite-magnetite and kaolinite-limonite.

CD-17

Started: September 30, 1973

Finished: October 6, 1973

Location: 304N/212W

Dip and Azimuth: -90^{o}

Elevation: 3,800 feet

Length of Hole: 603 feet

Purpose of Hole: To test the centre of an area of low copper and molybdenum soil values ringed by anomalous values.

Remarks: Assay results for CD-17 were similar to those for CD-15 - minor copper as disseminated chalcopyrite over the whole intersection (approx. 0.05%) with minor molybdenum (approx. 0.025%) over narrow widths in veins with quartz and pyrite. No correlation of molybdenum with rock type was noted. On the whole, the intersection was less altered and less mineralized than CD-15.

SUMMARY

The three 1973 holes totalling 1,896 feet of BQ wireline drilling were spotted to test the centres of rings of copper and molybdenum soil anomalies, in three areas of geochemical anomalies on the property. The results indicate that the secondary dispersion of copper and molybdenum has not followed the pattern indicated by certain other porphyry environments, e.g., Tyrone, New Mexico.

The Rusk Creek zone is thought to represent the top of porphyry-style mineralization as described by Lowell and Guilbert in 1970. The zone is apparently characterized by vein chalcopyrite, molybdenite, sphalerite and galena indicative of the margins of a porphyry environment and yet apparently concentric metal zoning is present. The conclusion is that the zone represents the top of such mineralization rather than the side, assuming the vertical, cylindrical body of Lowell & Guilbert.

The Caribou Mountain zone (CD-17, etc.) is apparently a low grade (0.1%) chalcopyrite dissemination, with non-pervasive molybdenite-silica veinlets. The zone is centred around approximately 325N, 215W with a diameter of possibly one mile.

The South Fork zone (CD-9, etc.) is generally better mineralized than the Caribou zone with some good intersections of 0.2% copper and 0.02% molybdenum. The zone may be elongate, east-west trending, and centred around 220N, 175W.

RECOMMENDATIONS

The author recommends a program similar to the 1973 program, consisting of 3 holes for a total of 2,000 feet of BQ wireline diamond drilling, approximate cost $40,000.

CD-18 at 216N, 172W; -90° to 800 feet, as recommended in the 1972 report. This hole could test the extension of the South Fork zone east of CD-9.

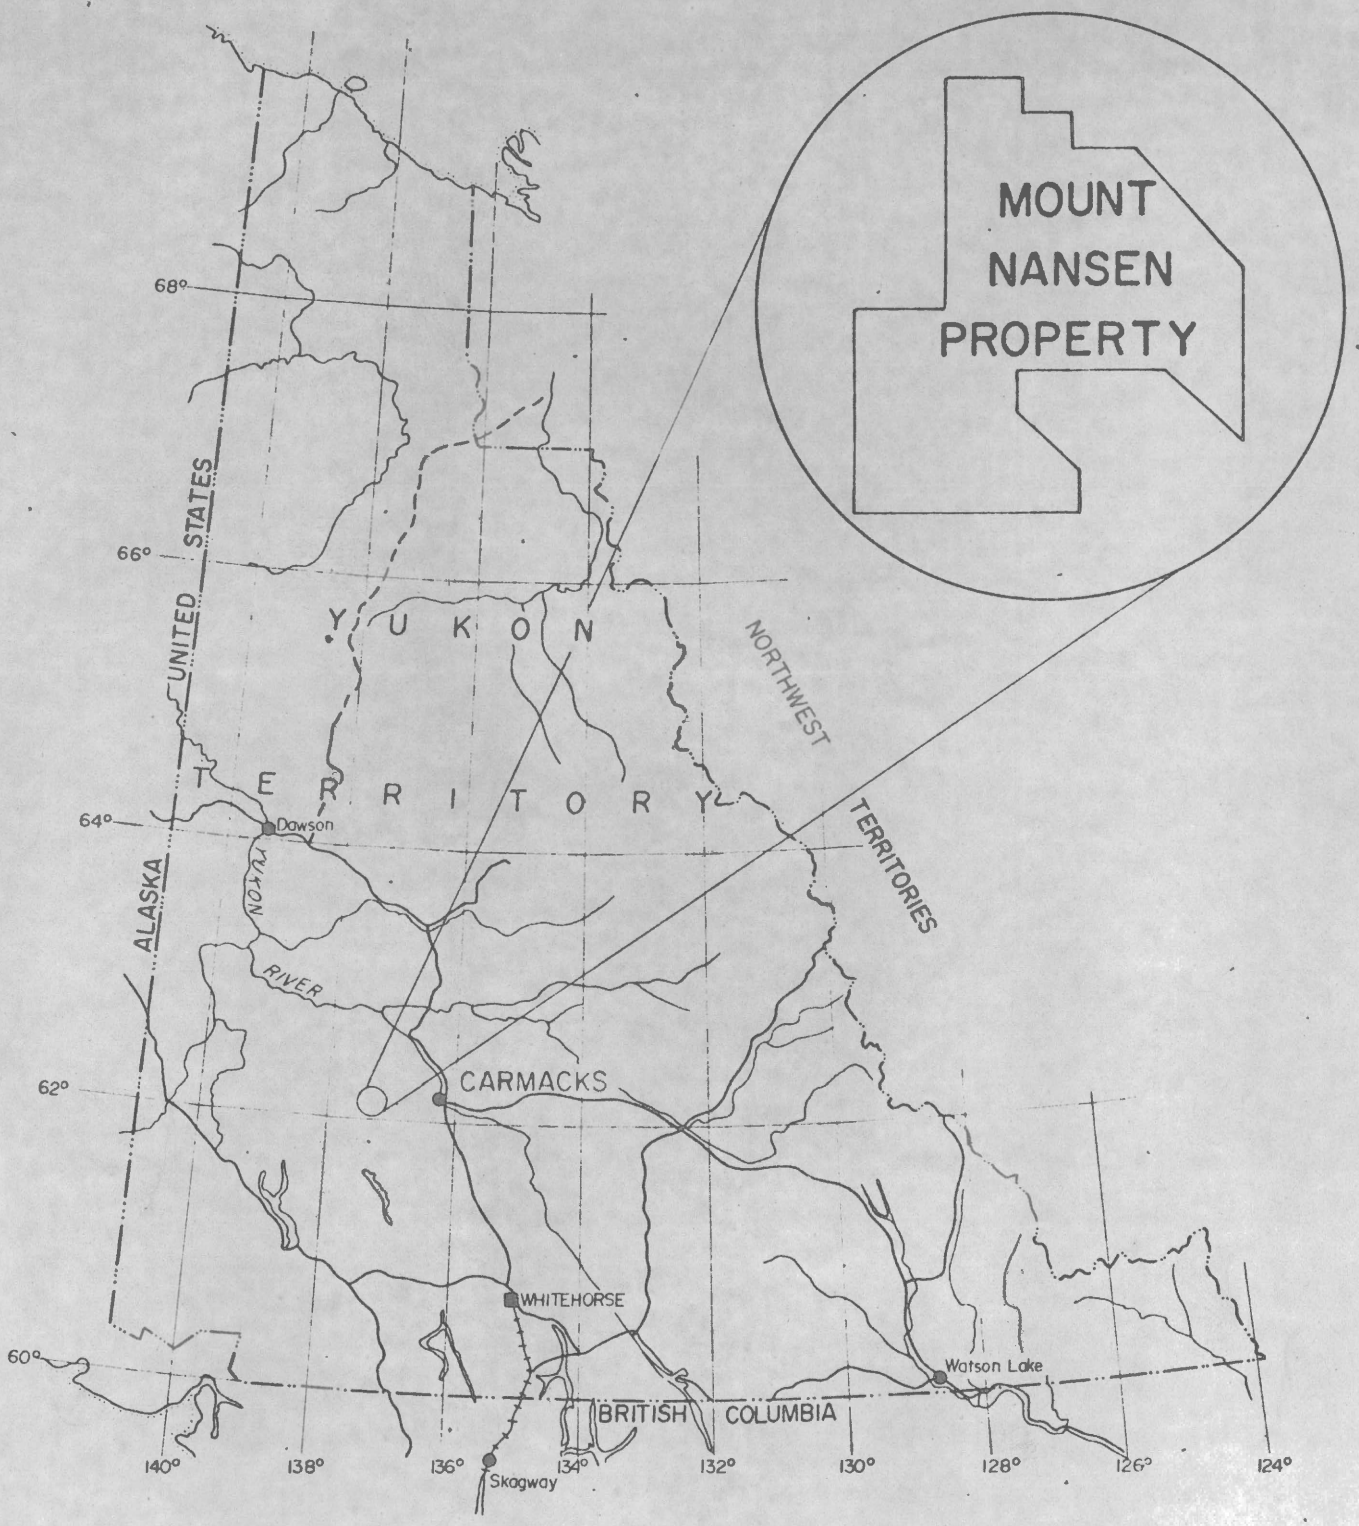

CD-19 at 192N, 174W; -90° to 600 feet, to test the centre of a large area (diameter approximately one mile) of untested anomalous I.P. and geochemical response.

CD-20 at 320N, 212W; -90° to 600 feet, to test the inferred centre of the Caribou Mountain zone, and the centre of an untested area (diameter approximately half a mile) of anomalous I.P. and geochemical response.

Should further funds be available, consideration should be given to deep drilling in the centres of the three zones.

Respectfully submitted,

P. F. Lewis, B.Sc.

			BW casing to 100'							
0	100	0	Overburden							
100	145	98%	Good recovery. 6" sections of core common. Silicified breccia. Sub-angular fragments of quartz rich granodiorite (adamellite) and lesser quartz feldspar porphyry. Fragments make up ≈ 70% or rock and commonly of pebble-cobble size. Matrix is grey highly siliceous rock flour?, microcrystalline. Silicates are strongly argillized (Kaolin), no mafics remain although there is a trace of chlorite. Fragments have thin white cooked rims. Section shows evidence for at least two generations of primary sulphide deposition. Some fragments have thin pyrite fracture fillings which are cut by matrix. Disseminated pyrite occurs (1-4%) throughout rock. Rare chalcopyrite. Chalcocite-covellite thinly coats pyrite at 102, 104, 108, 109. Black manganese? looking films occur on fracture planes to 126.	100	110	10	11069	0.03	0.001
